Introduction to dplyr

2015-06-15

When working with data you must:

- Figure out what you want to do.
- Precisely describe what you want in the form of a computer program.
- Execute the code.

The dplyr package makes each of these steps as fast and easy as possible by:

- Elucidating the most common data manipulation operations, so that your options are helpfully constrained when thinking about how to tackle a problem.
- Providing simple functions that correspond to the most common data manipulation verbs, so that you can easily translate your thoughts into code.
- Using efficient data storage backends, so that you spend as little time waiting for the computer as possible.

The goal of this document is to introduce you to the basic tools that dplyr provides, and show how you to apply them to data frames. Other vignettes provide more details on specific topics:

- databases: as well as in memory data frames, dplyr also connects to databases. It allows
 you to work with remote, out-of-memory data, using exactly the same tools, because dplyr
 will translate your R code into the appropriate SQL.
- o benchmark-baseball: see how dplyr compares to other tools for data manipulation on a realistic use case.
- o window-functions: a window function is a variation on an aggregation function. Where an aggregate function uses n inputs to produce 1 output, a window function uses n inputs to produce n outputs.

Data: nycflights13

To explore the basic data manipulation verbs of dplyr, we'll start with the built in nycflights13 data frame. This dataset contains all 336776 flights that departed from New York City in 2013. The data comes from the US <u>Bureau of Transportation Statistics</u>, and is documented in ?nycflights13

```
library(nycflights13)
dim(flights)
#> [1] 336776      16
head(flights)
#> Source: Local data frame [6 x 16]
#>
```

```
year month day dep_time dep_delay arr_time arr_delay carrier tailnum
#>
#> 1 2013
                                              830
                                                         11
                                                                     N14228
                          517
                                                                 IJΔ
#> 2 2013
               1
                   1
                          533
                                       4
                                              850
                                                         20
                                                                 UΑ
                                                                     N24211
#> 3 2013
               1
                          542
                                       2
                                              923
                                                         33
                                                                 AA
                                                                     N619AA
#> 4 2013
                          544
               1
                                      -1
                                             1004
                                                        -18
                                                                 В6
                                                                    N804JB
                                     . . .
#> Variables not shown: flight (int), origin (chr), dest (chr), air_time
     (dbl), distance (dbl), hour (dbl), minute (dbl)
```

dplyr can work with data frames as is, but if you're dealing with large data, it's worthwhile to convert them to a tbl_df: this is a wrapper around a data frame that won't accidentally print a lot of data to the screen.

Single table verbs

Dplyr aims to provide a function for each basic verb of data manipulating:

```
o filter() (and slice())
o arrange()
o select() (and rename())
o distinct()
o mutate() (and transmute())
o summarise()
o sample_n() and sample_frac()
```

If you've used plyr before, many of these will be familar.

Filter rows with filter()

filter() allows you to select a subset of the rows of a data frame. The first argument is the name of the data frame, and the second and subsequent are filtering expressions evaluated in the context of that data frame:

For example, we can select all flights on January 1st with:

```
filter(flights, month == 1, day == 1)
#> Source: local data frame [842 x 16]
#>
     year month day dep_time dep_delay arr_time arr_delay carrier tailnum
#> 1 2013
                   1
                          517
                                      2
                                                        11
                                                                UA N14228
                                             830
#> 2 2013
                                                        20
               1
                   1
                          533
                                      4
                                             850
                                                                UA N24211
#> 3 2013
               1
                   1
                          542
                                      2
                                             923
                                                        33
                                                                AA N619AA
#> 4 2013
              1
                   1
                          544
                                     -1
                                            1004
                                                       -18
                                                                B6 N804JB
                                    . . .
#> Variables not shown: flight (int), origin (chr), dest (chr), air_time
```

6/19/15, 7:03 PM 2 of 14

```
#> (dbl), distance (dbl), hour (dbl), minute (dbl)
```

This is equivalent to the more verbose:

```
flights[flights$month == 1 & flights$day == 1, ]
```

filter() works similarly to subset() except that you can give it any number of filtering conditions which are joined together with & (not && which is easy to do accidentally!). You can use other boolean operators explicitly:

```
filter(flights, month == 1 | month == 2)
```

To select rows by position, use slice():

```
slice(flights, 1:10)
#> Source: Local data frame [10 x 16]
#>
#>
     year month day dep_time dep_delay arr_time arr_delay carrier tailnum
#> 1 2013
                          517
                                      2
                                                         11
                                                                 UA N14228
               1
                   1
                                              830
#> 2 2013
               1
                   1
                          533
                                              850
                                                         20
                                                                 UA N24211
#> 3 2013
                          542
                                                         33
                                                                 AA N619AA
                                      2
                                             923
#> 4 2013
               1
                   1
                          544
                                                                 B6 N804JB
                                      -1
                                             1004
                                                        -18
                                    . . .
#> Variables not shown: flight (int), origin (chr), dest (chr), air_time
     (dbl), distance (dbl), hour (dbl), minute (dbl)
```

Arrange rows with arrange()

arrange() works similarly to filter() except that instead of filtering or selecting rows, it reorders them. It takes a data frame, and a set of column names (or more complicated expressions) to order by. If you provide more than one column name, each additional column will be used to break ties in the values of preceding columns:

```
arrange(flights, year, month, day)
#> Source: local data frame [336,776 x 16]
#>
     year month day dep_time dep_delay arr_time arr_delay carrier tailnum
#> 1 2013
                                                         11
                          517
                                      2
                                             830
                                                                 UA N14228
#> 2 2013
                          533
                                      4
                                                         20
               1
                   1
                                             850
                                                                 UA N24211
#> 3 2013
               1
                   1
                          542
                                      2
                                             923
                                                         33
                                                                    N619AA
#> 4 2013
               1
                          544
                                     -1
                                            1004
                                                        -18
                                                                 В6
                                                                    N804JB
#> Variables not shown: flight (int), origin (chr), dest (chr), air time
    (dbl), distance (dbl), hour (dbl), minute (dbl)
```

6/19/15, 7:03 PM 3 of 14

Use desc() to order a column in descending order:

```
arrange(flights, desc(arr_delay))
#> Source: local data frame [336,776 x 16]
#>
#>
     year month day dep_time dep_delay arr_time arr_delay carrier tailnum
                 9
                          641
                                   1301
#> 1 2013
                                            1242
                                                      1272
                                                                HA N384HA
#> 2 2013
                         1432
               6 15
                                   1137
                                            1607
                                                      1127
                                                                MQ N504MQ
#> 3 2013
                        1121
              1 10
                                   1126
                                            1239
                                                      1109
                                                                MQ N517MQ
#> 4 2013
               9 20
                         1139
                                   1014
                                            1457
                                                      1007
                                                                AA N338AA
#> .. ...
           . . . . . . .
                          . . .
                                    . . .
                                             . . .
#> Variables not shown: flight (int), origin (chr), dest (chr), air time
    (dbl), distance (dbl), hour (dbl), minute (dbl)
```

dplyr::arrange() works the same way as plyr::arrange(). It's a straighforward wrapper around order() that requires less typing. The previous code is equivalent to:

```
flights[order(flights$year, flights$month, flights$day), ]
flights[order(desc(flights$arr_delay)), ]
```

Select columns with select()

Often you work with large datasets with many columns where only a few are actually of interest to you. select() allows you to rapidly zoom in on a useful subset using operations that usually only work on numeric variable positions:

```
# Select columns by name
select(flights, year, month, day)
#> Source: Local data frame [336,776 x 3]
#>
#>
     year month day
#> 1 2013
#> 2 2013
              1
#> 3 2013
              1
                   1
#> 4 2013
#> .. ...
            . . . . . . .

#> 4
       BQN
#> ... ...
#> Variables not shown: air_time (dbl), distance (dbl), hour (dbl), minute
     (dbL)
```

This function works similarly to the select argument to the base::subset(). It's its own function in dplyr, because the dplyr philosophy is to have small functions that each do one thing well.

There are a number of helper functions you can use within <code>select()</code>, like <code>starts_with()</code>, <code>ends_with()</code>, <code>matches()</code> and <code>contains()</code>. These let you quickly match larger blocks of variable that meet some criterion. See <code>?select</code> for more details.

You can rename variables with select() by using named arguments:

```
select(flights, tail_num = tailnum)
#> Source: Local data frame [336,776 x 1]
#>
#> tail_num
#> 1  N14228
#> 2  N24211
#> 3  N619AA
#> 4  N804JB
#> ...
```

But because select() drops all the variables not explicitly mentioned, it's not that useful. Instead, use rename():

```
rename(flights, tail_num = tailnum)
#> Source: Local data frame [336,776 x 16]
#>
#> year month day dep_time dep_delay arr_time arr_delay carrier tail_num
```

6/19/15, 7:03 PM 5 of 14

```
#> 1 2013

                  1
                         542
                                     2
                                            923
                                                       33
                                                               AA
                                                                    N619AA
#> 4 2013
              1 1
                         544
                                    -1
                                           1004
                                                      -18
                                                               В6
                                                                    N804JB
#> .. ...
#> Variables not shown: flight (int), origin (chr), dest (chr), air_time
    (dbl), distance (dbl), hour (dbl), minute (dbl)
```

Extract distinct (unique) rows

A common use of select() is to find out which values a set of variables takes. This is particularly useful in conjunction with the distinct() verb which only returns the unique values in a table.

```
distinct(select(flights, tailnum))
#> Source: local data frame [4,044 x 1]
#>
#>
     tailnum
      N14228
#> 1
      N24211
#> 3
      N619AA
#> 4
      N804JB
distinct(select(flights, origin, dest))
#> Source: local data frame [224 x 2]
#>
#>
      origin dest
#> 1
        EWR IAH
#> 2
        LGA IAH
#> 3
        JFK MIA
#> 4
        JFK BQN
#> ..
```

(This is very similar to base::unique() but should be much faster.)

Add new columns with mutate()

As well as selecting from the set of existing columns, it's often useful to add new columns that are functions of existing columns. This is the job of mutate():

```
mutate(flights,
   gain = arr_delay - dep_delay,
   speed = distance / air_time * 60)
#> Source: Local data frame [336,776 x 18]
```

6/19/15, 7:03 PM 6 of 14

```
#>
#>
      year month day dep_time dep_delay arr_time arr_delay carrier tailnum
#> 1
     2013
               1
                   1
                           517
                                       2
                                               830
                                                          11
                                                                   UA N14228
#> 2
      2013
               1
                   1
                           533
                                       4
                                               850
                                                          20
                                                                   UΑ
                                                                      N24211
#> 3
      2013
                           542
                                       2
                                               923
                                                          33
                                                                      N619AA
               1
                   1
                                                                   AA
#> 4 2013
               1
                   1
                           544
                                       -1
                                              1004
                                                         -18
                                                                       N804JB
                                                                   В6
#> .. ...
             . . . . . .
#> Variables not shown: flight (int), origin (chr), dest (chr), air_time
     (dbl), distance (dbl), hour (dbl), minute (dbl), gain (dbl), speed (dbl)
```

dplyr::mutate() works the same way as plyr::mutate() and similarly to base::transform(). The key difference between mutate() and transform() is that mutate allows you to refer to columns that you just created:

```
mutate(flights,
   gain = arr_delay - dep_delay,
   gain per hour = gain / (air time / 60)
 )
 #> Source: Local data frame [336,776 x 18]
 #>
 #>
       year month day dep_time dep_delay arr_time arr_delay carrier tailnum
                                         2
 #> 1 2013
                     1
                            517
                                                830
                                                           11
                                                                    UA N14228
 #> 2 2013
                 1
                     1
                            533
                                         4
                                                850
                                                           20
                                                                    UA N24211
 #> 3 2013
                                                923
                1
                     1
                            542
                                         2
                                                           33
                                                                    AA N619AA
 #> 4
       2013
                            544
                                        -1
                                               1004
                                                          -18
                                                                        N804JB
                                                                    B6
 #> .. ...
                            . . .
                                                . . .
                                                          . . .
 #> Variables not shown: flight (int), origin (chr), dest (chr), air_time
      (dbl), distance (dbl), hour (dbl), minute (dbl), gain (dbl),
 #>
      gain per hour (dbl)
 transform(flights,
   gain = arr_delay - delay,
   gain_per_hour = gain / (air_time / 60)
 )
 #> Error: object 'gain' not found
If you only want to keep the new variables, use transmute():
 transmute(flights,
   gain = arr_delay - dep_delay,
   gain_per_hour = gain / (air_time / 60)
 #> Source: local data frame [336,776 x 2]
 #>
 #>
       gain gain_per_hour
```

6/19/15, 7:03 PM 7 of 14

```
#> 1 9 2.378855

#> 2 16 4.229075

#> 3 31 11.625000

#> 4 -17 -5.573770

#> ... ...
```

Summarise values with summarise()

The last verb is summarise(), which collapses a data frame to a single row. It's not very useful yet:

```
summarise(flights,
  delay = mean(dep_delay, na.rm = TRUE))
#> Source: Local data frame [1 x 1]
#>
#> delay
#> 1 12.63907
```

This is exactly equivalent to plyr::summarise().

Randomly sample rows with sample_n() and sample_frac()

You can use sample_n() and sample_frac() to take a random sample of rows, either a fixed number for sample n() or a fixed fraction for sample frac().

```
sample_n(flights, 10)
#> Source: local data frame [10 x 16]
#>
     year month day dep_time dep_delay arr_time arr_delay carrier tailnum
#> 1 2013
              9 26
                        1816
                                    16
                                           1932
                                                       12

Use replace = TRUE to perform a bootstrap sample, and optionally weight the sample with the weight argument.

Commonalities

You may have noticed that all these functions are very similar:

- The first argument is a data frame.
- The subsequent arguments describe what to do with it, and you can refer to columns in the data frame directly without using \$.
- o The result is a new data frame

Together these properties make it easy to chain together multiple simple steps to achieve a complex result.

These five functions provide the basis of a language of data manipulation. At the most basic level, you can only alter a tidy data frame in five useful ways: you can reorder the rows (arrange()), pick observations and variables of interest (filter() and select()), add new variables that are functions of existing variables (mutate()) or collapse many values to a summary (summarise()). The remainder of the language comes from applying the five functions to different types of data, like to grouped data, as described next.

Grouped operations

These verbs are useful, but they become really powerful when you combine them with the idea of "group by", repeating the operation individually on groups of observations within the dataset. In dplyr, you use the <code>group_by()</code> function to describe how to break a dataset down into groups of rows. You can then use the resulting object in exactly the same functions as above; they'll automatically work "by group" when the input is a grouped.

The verbs are affected by grouping as follows:

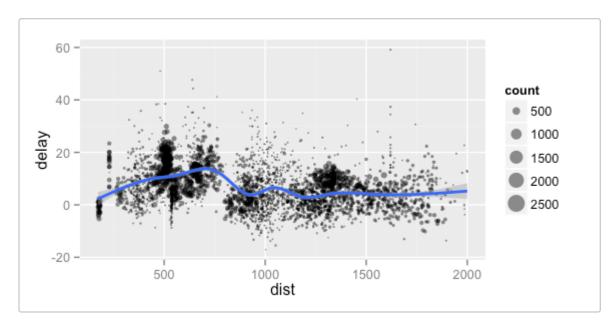

- grouped select() is the same as ungrouped select(), excepted that retains grouping variables are always retained.
- o grouped arrange() orders first by grouping variables
- o mutate() and filter() are most useful in conjunction with window functions (like rank(), or min(x) == x), and are described in detail in vignette("window-functions").
- o sample_n() and sample_frac() sample the specified number/fraction of rows in each group.
- slice() extracts rows within each group.
- o summarise() is easy to understand and very useful, and is described in more detail below.

6/19/15, 7:03 PM 9 of 14

In the following example, we split the complete dataset into individual planes and then summarise each plane by counting the number of flights (count = n()) and computing the average distance (dist = mean(Distance, na.rm = TRUE)) and delay (delay = mean(ArrDelay, na.rm = TRUE)). We then use ggplot2 to display the output.

```
by_tailnum <- group_by(flights, tailnum)
delay <- summarise(by_tailnum,
    count = n(),
    dist = mean(distance, na.rm = TRUE),
    delay = mean(arr_delay, na.rm = TRUE))
delay <- filter(delay, count > 20, dist < 2000)

# Interestingly, the average delay is only slightly related to the
# average distance flown by a plane.
ggplot(delay, aes(dist, delay)) +
    geom_point(aes(size = count), alpha = 1/2) +
    geom_smooth() +
    scale_size_area()</pre>
```

You use summarise() with **aggregate functions**, which take a vector of values, and return a single number. There are many useful functions in base R like min(), max(), mean(), sum(), sd(), median(), and IQR(). dplyr provides a handful of others:

- o n(): number of observations in the current group
- o n_distinct(x): count the number of unique values in x.
- o first(x), last(x) and nth(x, n) these work similarly to x[1], x[length(x)], and x[n] but give you more control of the result if the value isn't present.

For example, we could use these to find the number of planes and the number of flights that go to each possible destination:

```
destinations <- group_by(flights, dest)</pre>
summarise(destinations,
  planes = n_distinct(tailnum),
  flights = n()
#> Source: local data frame [105 x 3]
#>
      dest planes flights
#>
#> 1
      ABQ
              108
#> 2
      ACK
              58
                      265
#> 3
      ALB
             172
                     439
#> 4
      ANC
             6
                      8
#> ... ...
              . . .
                      . . .
```

You can also use any function that you write yourself. For performance, dplyr provides optimised C++ versions of many of these functions. If you want to provide your own C++ function, see the hybrid-evaluation vignette for more details.

When you group by multiple variables, each summary peels off one level of the grouping. That makes it easy to progressively roll-up a dataset:

```
daily <- group_by(flights, year, month, day)</pre>
(per_day <- summarise(daily, flights = n()))</pre>
#> Source: local data frame [365 x 4]
#> Groups: year, month
#>
#>
     year month day flights
#> 1 2013
              1 1
                        842
#> 2 2013
                 2
                        943
              1
#> 3 2013
              1 3
                        914
#> 4 2013
            1 4
                        915
#> ... ...
(per_month <- summarise(per_day, flights = sum(flights)))</pre>
#> Source: local data frame [12 x 3]
#> Groups: year
#>
     year month flights
#> 1 2013
              1 27004
#> 2 2013
              2 24951
#> 3 2013
              3 28834
#> 4 2013
                 28330
#> .. ...
(per_year <- summarise(per_month, flights = sum(flights)))</pre>
#> Source: local data frame [1 x 2]
#>
   year flights
```

```
#> 1 2013 336776
```

However you need to be careful when progressively rolling up summaries like this: it's ok for sums and counts, but you need to think about weighting for means and variances, and it's not possible to do exactly for medians.

Chaining

The dplyr API is functional in the sense that function calls don't have side-effects, and you must always save their results. This doesn't lead to particularly elegant code if you want to do many operations at once. You either have to do it step-by-step:

```
a1 <- group_by(flights, year, month, day)
a2 <- select(a1, arr_delay, dep_delay)
a3 <- summarise(a2,
    arr = mean(arr_delay, na.rm = TRUE),
    dep = mean(dep_delay, na.rm = TRUE))
a4 <- filter(a3, arr > 30 | dep > 30)
```

Or if you don't want to save the intermediate results, you need to wrap the function calls inside each other:

```
filter(
 summarise(
   select(
      group_by(flights, year, month, day),
      arr_delay, dep_delay
   ),
   arr = mean(arr_delay, na.rm = TRUE),
   dep = mean(dep delay, na.rm = TRUE)
 ),
 arr > 30 | dep > 30
)
#> Source: local data frame [49 x 5]
#> Groups: year, month
#>
#>
     year month day
                         arr
                                  dep
#> 1 2013
              1 16 34.24736 24.61287
#> 2 2013
             1 31 32.60285 28.65836
#> 3 2013
              2 11 36.29009 39.07360
#> 4 2013
              2 27 31.25249 37.76327
           . . . . . .
```

This is difficult to read because the order of the operations is from inside to out, and the arguments are a long way away from the function. To get around this problem, dplyr provides the

%>% operator. x %>% f(y) turns into f(x, y) so you can use it to rewrite multiple operations so you can read from left-to-right, top-to-bottom:

```
flights %>%
  group_by(year, month, day) %>%
  select(arr_delay, dep_delay) %>%
  summarise(
    arr = mean(arr_delay, na.rm = TRUE),
    dep = mean(dep_delay, na.rm = TRUE)
) %>%
  filter(arr > 30 | dep > 30)
```

Other data sources

As well as data frames, dplyr works with data stored in other ways, like data tables, databases and multidimensional arrays.

Data table

dplyr also provides <u>data table</u> methods for all verbs. If you're using data.tables already this lets you use dplyr syntax for data manipulation, and data.table for everything else.

For multiple operations, data.table can be faster because you usually use it with multiple verbs at the same time. For example, with data table you can do a mutate and a select in a single step, and it's smart enough to know that there's no point in computing the new variable for the rows you're about to throw away.

The advantages of using dplyr with data tables are:

- For common data manipulation tasks, it insulates you from reference semantics of data.tables, and protects you from accidentally modifying your data.
- Instead of one complex method built on the subscripting operator ([), it provides many simple methods.

Databases

dplyr also allows you to use the same verbs with a remote database. It takes care of generating the SQL for you so that you can avoid the cognitive challenge of constantly swiching between languages. See the databases vignette for more details.

Compared to DBI and the database connection algorithms:

- it hides, as much as possible, the fact that you're working with a remote database
- you don't need to know any sql (although it helps!)
- o it abstracts over the many differences between the different DBI implementations

Multidimensional arrays / cubes

tbl_cube() provides an experimental interface to multidimensional arrays or data cubes. If you're using this form of data in R, please get in touch so I can better understand your needs.

Comparisons

Compared to all existing options, dplyr:

- abstracts away how your data is stored, so that you can work with data frames, data tables and remote databases using the same functions. This lets you think about what you want to achieve, not the logistics of data storage.
- it provides a thoughtful default print() method so you don't accidentally print pages of data to the screen (this was inspired by data table's output)

Compared to base functions:

- dplyr is much more consistent; functions have the same interface so that once you've mastered one, you can easily pick up the others
- o base functions tend to be based around vectors; dplyr is centered around data frames

Compared to plyr:

- o dplyr is much much faster
- it provides a better thought out set of joins
- it only provides tools for working with data frames (e.g. most of dplyr is equivalent to ddply() + various functions, do() is equivalent to dlply())

Compared to virtual data frame approaches:

- it doesn't pretend that you have a data frame: if you want to run Im etc, you'll still need to manually pull down the data
- it doesn't provide methods for R summary functions (e.g. mean(), or sum())
